1 Introduction

Under a previous contract, several estimators of the proportions of active people in Swiss districts were compared in model-based and design-based simulation studies. These simulation studies were performed in a realistic way, using data from the Structural Survey. Based on the obtained results, the empirical best linear unbiased predictor (EBLUP) under a linear mixed model (LMM) was the selected estimator, together with its benchmarked (BM) version that adds up to the corresponding national estimate. Parametric, non parametric and mixed bootstrap procedures were proposed for estimation of the mean squared error (MSE) of these two small area estimators. Simulation studies were carried out to analyze the performance of the mentioned bootstrap procedures for estimation of the MSE. Normality-based confidence intervals obtained using benchmarked EBLUPs based on the LMM together with MSE estimates based on the mixed bootstrap procedures were also studied. The actual coverage and length of these confidence intervals was analyzed through model-based and design-based simulation studies. We also analyzed the coverage and length of confidence intervals based on GREG estimates (considering GREG weights as fixed) and using analytical MSE estimates of GREG estimators.

The selected estimation methods were used to produce estimates of the proportions of economically active people in Swiss districts, of their MSEs using the two mixed bootstrap approaches, and of confidence intervals (CIs) based on these estimates. This was done using the data from the Structural Survey and the values of the auxiliary variables from the registers.

This report describes a design-based simulation experiment that studies the performance of EBLUPs based on LMM, called hereafter LMM estimates for brevity, for estimation of the proportions of active people in Swiss communes, which are nested in districts and thus represent a further level of disaggregation. We compare LMM estimates for the proportions of active people in the communes using the benchmarked estimates, when benchmarking is performed both at the national and at the canton levels. We also apply the LMM estimates (raw and with both types of benchmarking) to the real data from the Structural survey and the auxiliary information in the registers. Finally, we obtain MSE estimates and normality-based confidence intervals, using the parametric design bootstrap (PDB) procedure described in the report of Phase I of this project. That report showed that PDB MSE estimates track the true design MSE for areas with sample size over 100.

2 Available data

We recall that the available data comes from three sources: the Structural Survey and two registers, namely the STATPOP and OASI registers. The Structural Survey measures the target variable (active/non active) and a number of useful auxiliary variables for a sample of 286,015 Swiss permanent residents aged 15 or more that live in private households. The STATPOP and OASI registers contain only a number of auxiliary variables, but for the whole population of $N = 6,662,333$ Swiss residents aged over 15. The total number of communes in the registers is 2485, out of which 2475 are observed in the Structural

survey. From the latter communes, the population sizes of the communes range from $\min(N_d) = 12$ to $\max(N_d) = 318,700$, with an average commune population size of $\bar{N} = 2,692$. A summary of the commune sample sizes in the Structural Survey is given in Table 1. The sample sizes are highly right skewed, with only some communes having very large sample sizes. Certainly, the mean sample size turns out to be larger than the third quartile, because it is affected by the mentioned extreme sample sizes. In fact, looking at Table 2 showing the number of communes with sample sizes below selected levels, we can see that more than 2/3 of the communes have a sample size below 100, more than half have sample size below 50 and more than a quarter have sample size below 20. Thus, communes are clearly suitable for application of small area estimation techniques.

Table 1: Summary of commune sample sizes in the Structural Survey

Min	Q_1	Median	Mean	Q_3	Max
1	18	44	115.6	111.5	9510

Table 2: Num. communes with sample sizes below selected levels

$n_d \leq$	10	20	30	40	50	100
# communes	356	697	964	1173	1337	1792

3 Model selection

As in the previous work, since the target variable is observed only in the Structural Survey, the model is fitted using the Structural Survey data and the records of the registers that appear also in the Structural Survey. For estimation of the proportions of active people in the communes, the first step is to find a suitable model. For this, we first consider the model that was previously obtained for estimation in the districts. We include in the model for communes exactly the same auxiliary variables that were included in the model for estimation in districts, except that the random effects are now for the communes rather than for districts. In the fitted model, all the auxiliary variables remained to be significant.

After fitting the model, we carried out model diagnostics. Figure 1 (top-left) displays a qqplot of the estimated commune effects for all the communes. This plot shows that the distribution of the estimated commune effects has slightly heavier tails than those of the normal distribution. Take into account that many communes have a very small sample size and therefore the few individuals observed in those communes might not be very representative of the whole commune. When removing the communes where direct estimators have a CV greater than 10%, the qqplot (top-right) shows a slightly different picture, with practically all points closer to the equality line and therefore a distribution closer to normal. Still, at the bottom-left corner of these two plots we find a point that is further apart and does not follow the pattern of the other points. This point corresponds to the commune num. 5192 (Lugano), which belongs to District num. 2105 (Lugano) in the canton of Ticino. The population size of this commune is 47,316 and the sample size is 2,901. The estimated effect of this commune is smaller than it should be according to

the normal assumption of commune effects in the model. Thus, it is an outlier, whose proportion of active people is not well explained by the considered model. To avoid a bias in the estimated proportion for this commune and since its sample size is rather large, we introduced a fixed effect for it in the model; that is, we included a dummy auxiliary variable, called Commune5192, taking value one for the individuals of this commune and zero for the others. The estimated coefficient for this new variable turns out to be negative and hence the estimated percentage of actives in this commune is smaller than it should be according to the values of the other covariates in the model. After fitting the model with a fixed effect for this commune, the resulting qqplot of the commune effects, shown at the bottom of Figure 1, shows no outlying commune any more. The complete list of auxiliary variables included in the fitted LMM for communes can be seen in Table 3. The fitted regression coefficients of the selected LMM are included in Appendix 8. These estimated coefficients turn out to be very close to those obtained in the model that was fitted to the districts, which gives credibility to the resulting fitted model.

Table 3: Variables in the model for communes

active	1=active 0=inactive
commune	there are 2475 in the Structural survey
District1724	1=District nr 1724 / 0=otherwise
Commune5192	1=Commune nr 5192 (Lugano)/ 0=otherwise
Strata1	0=Strata with large sampling weight median, 1=otherwise
age group	15, [16,20), [20,60), [60,64), 64, ≥ 65
gender	male (1) / female (2)
nationality	Not swiss (1) / Swiss (2)
civil status	1 = single, unmarried, 2 = married, in a registered partnership, 3 = widow/er, 4 = divorced, partnership dissolved
OASItri	1 = in OASI only Jan-March, 0 = otherwise
Income	unknown (In OASI = no), (0,12000], (12000,24000], (24000,48000], (48000,72000], (72000,96000], (96000,120000], > 120000
Household Size	1, 2, [3,5], [6,10] >10
secondary residence	no (1) / yes (2)

4 Design-based simulation on the Structural Survey data

In this section we describe a design-based simulation study, in which samples are drawn from a fixed population. As fixed population, we consider the Structural survey data, which contains the values of the target and auxiliary variables, but removing the communes with CV of direct estimators greater than 10%, together with communes with sample size equal to 1 (CV not available) and those with estimated proportion of actives equal to 1 (CV=0). According to this, from the total of 2475 communes observed in the Structural Survey, 1248 of them were removed. It is interesting to note that not all the

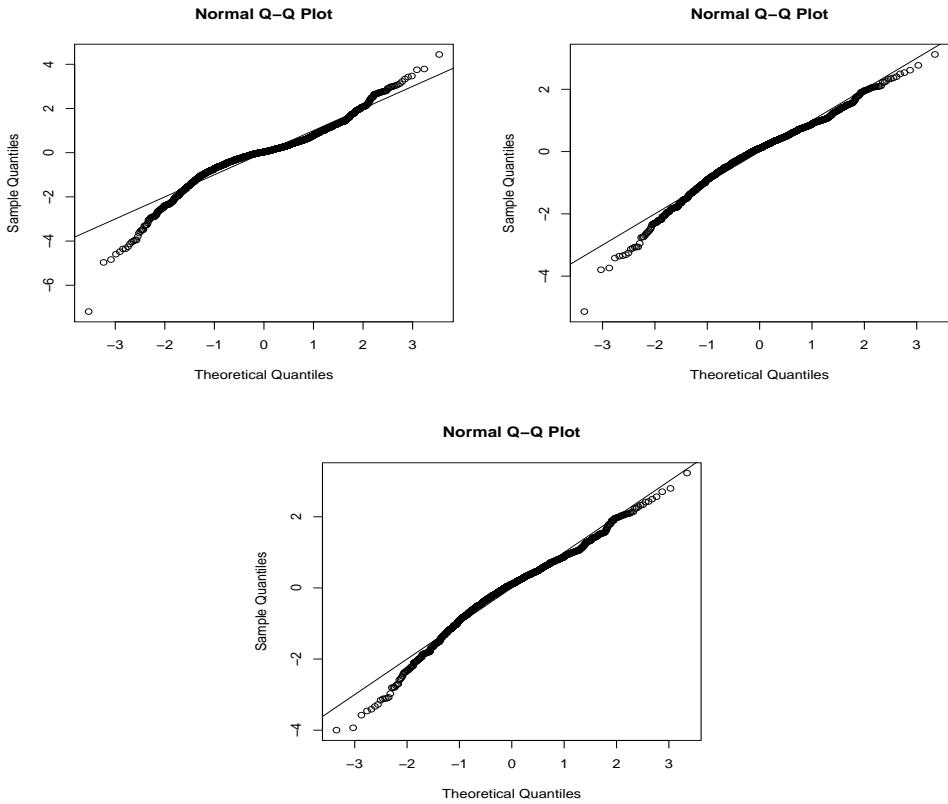

Figure 1: QQplot for all data (left-top), qqplot on reduced sample of 1227 communes (top-right) and qqplot on reduced sample of 1227 communes based on the model with "Commune5192" as fix effect (bottom).

removed communes have an extremely small sample size, see Table 4 for a summary of the sample sizes of the removed communes.

Table 4: Summary of sample sizes of removed communes

Min	Q_1	Median	Mean	Q_3	Max
1	9	18	21.83	31	92

Thus, after removing the above communes, the remaining number of communes in the Structural Survey is $D = 1227$ and, from those, the smallest commune contains 11 individuals. This minimum "population" size is realistic because the smallest population size in the entire data set is 12. Like this commune, some of the remaining communes still have a small sample size even if their CV is below 10% because their estimated proportions of active people are large. In fact, from the remaining communes, those with sample size of at most 20 have a minimum estimated proportion of actives of 0.84, whereas the minimum estimated proportion in the whole Structural Survey is 0.456. From the considered fixed population, we draw $L = 500$ samples. The allocation of sample sizes

in the communes is as follows. Sorting the communes from smallest to largest population size, we take $\min(n_d) = 1$ observation from the smallest commune (smallest sample size in the original data) and then we increase the sample sizes by one unit for each commune, but repeating the same sample size for those communes that share the same population size (otherwise the sample size would exceed the population size). More precisely, let $N_{1:D}, \dots, N_{D:D}$ be the population sizes sorted from smallest to largest. The sample sizes are then taken as $n_{k:D} = n_{(k-1):D} + 1_{\{N_{k:D} - N_{(k-1):D} > 0\}}$, where $1_{\{N_{k:D} - N_{(k-1):D} > 0\}} = 1$ if $N_{k:D} > N_{(k-1):D}$ and 0 if $N_{k:D} = N_{(k-1):D}$.

For each of the $L = 500$ samples, we computed unadjusted LMM estimators and LMM estimators with benchmarking at national and canton levels. The resulting adjustment factor for the benchmarked estimators at the national level, averaged across of the $L = 500$ samples was 1.0084, which means a very mild adjustment. The averaged adjustment factors for the benchmarked estimators at the canton level are given in Table 5 for each canton. These average adjustment factors are still rather close to 1 for all the cantons, which means small adjustments in average. Even if estimates are taking very similar values with and without the benchmarking adjustments, still such mild adjustments can have a visible influence in the relative biases of estimators, as we are going to see.

Table 5: Adjustment factors for benchmarked LMM estimates at the canton level averaged across the $L = 500$ samples.

1	2	3	4	5	6	7	8	9
1.0086	1.0101	1.0041	0.9901	0.9952	1.0089	0.9888	1.0259	1.0147
10	11	12	13	14	15	16	17	18
1.0055	1.0057	0.9822	1.0037	1.0162	1.0292	1.0105	1.0141	1.0015
19	20	21	22	23	24	25	26	
1.0090	1.0080	1.0028	1.0115	1.0036	1.0126	1.0203	1.0147	

Figure 2 displays a boxplot of the absolute relative biases (ARBs) of unadjusted LMM estimators and LMM estimators with benchmarking at national and canton levels. This plot shows no substantial differences between the ARBs of each type of estimator. Now compare Figures 3 and 4, displaying separately the results for the communes with sample size smaller than 100 and larger than 100 respectively. For the communes with sample size smaller than 100, the boxplots show again similar ARBs for the three types of LMM estimates. However, the boxplots for the communes with larger sample sizes show an increase in the ARBs of bechmarked estimates of about half percent point with respect to unadjusted LMM estimates. Moreover, the benchmarked estimates at the national level have smaller ARBs than those benchmarked at the canton level. Thus, benchmarking seems to be increasing slightly the design bias for the communes with sample size over 100, and this bias increases when the benchmarking is carried out at a more disaggregated level, probably because canton direct estimates have worse quality than national estimates. The same conclusions can be drawn when looking at the relative root MSEs (RRMSEs) of the estimators, see Figures 5, 6 and 7.

Just in case the outliers in Figures 5 and 6 are hiding the performance of the estimators

for the non-outliers, in Figures 8 and 9 we include exactly the same boxplots, but with the scale of the y -axis as in Figure 7. Still, in Figure 9, for the communes with sample sizes below 100, we see just very minor differences in the medians and the boxes for the three estimators. When looking at all the communes together in Figure 8, we see some slight differences, which must come from the communes with sample sizes above 100. Thus, here the largest differences due to benchmarking appear to be for the communes with sample sizes above 100.

Trying to gain more insight into the results, in Figure 10 we have plotted ARBs of GREGs, unadjusted LMM estimators and LMM estimators with benchmarking at national and canton levels, averaged for groups of communes with sample sizes in the intervals $[25k, 25(k+1)]$, $k = 0, 1, \dots, 28$. It is interesting to see that the unadjusted LMM estimators have smaller average ARB than GREGs for communes with sample sizes over 50. The reason must be that the model fits really well for those communes with a minimum number of observations. However, for communes with sample size below 50, this average design bias increases, reaching about 3.5%. Again, we can see that both types of benchmarking reduce the average ARB of LMM estimates by a little less than half percent point for the communes with smaller sample sizes ($n_d \leq 50$). In contrast, for the communes with larger sample sizes, benchmarking increases the average ARB by quantities slightly over half percent point, reaching the ARBs of the GREGs. This similarity of the ARBs of benchmarked estimates and GREGs is reasonable, since we are benchmarking to the GREGs at national or canton level. Let us now compare the two types of benchmarked estimates. For this, look at Figure 11, showing the same plot but without GREG estimates, so that we can distinguish better the lines for the other estimates. There are no great differences in design bias between the two types of benchmarked estimates, although benchmarked estimates at the national level have slightly smaller average ARB for the communes with larger sample sizes.

Figures 12–13 show the analogous plots for the RRMSEs. The increase in the RRMSE of the GREG estimators for the communes with larger sample sizes shown on the left side of Figure 12 is due to the fact that the sample sizes in this simulation study are not increasing proportionally to the “population sizes” of the communes and then sampling fractions are large for the communes with sample sizes around the center and small for the communes with small or large sample sizes (see Figure 14). This leads to larger MSEs of direct GREG estimators due to larger finite population corrections $(1 - n_d/N_d)$ for those communes with extreme sample sizes. Figure 12 shows that LMM estimators reduce the average RRMSE of GREG estimators by about a half. In the original Structural Survey, the overall sample size for fitting the model is considerably larger and thus gains will be much larger than in these simulations. Figure 13 shows the effects of benchmarking in the RRMSE. Again, we can see that benchmarking slightly decreases the RRMSE for those with smaller sample sizes ($n_d \leq 50$), but increases the RRMSE for communes with sample sizes above 50, with benchmarking at the national level giving slightly better results than benchmarking at the canton level for those communes.

Summarizing, we conclude that benchmarking produces a reduction of design bias and MSE for communes with small sample sizes ($n_d \leq 50$), and an increase for communes with larger sample sizes. Benchmarked estimates at the canton level are slightly worse

than those benchmarked at the national level.

These average conclusions are confirmed when looking at the individual results shown in Appendix 1. Since the number of communes is large ($D = 1227$), to make the points visible, each figure in this appendix represents the results for the subset of communes with sample size in the range shown in the labels of the x -axis. The first seven figures (Figures 21-27) represent, for each commune, ARBs of unadjusted LMM estimators and LMM estimators with benchmarking at canton and national level. Within each plot, the communes are sorted from left to right by decreasing sample sizes, as indicated in the labels of the x -axis. Each figure is accompanied by a table counting the number of communes with an ARB within a given range, for each type of estimator, see Tables 9–15. Figures 28-34 and Tables 16-22 represent the corresponding RRMSEs. The plots for communes with smaller sample sizes show a slight decrease in ARB and RRMSE of benchmarked estimates with respect to the unadjusted ones, whereas the plots for communes with larger sample size show an increase in ARB and RRMSE of benchmarked estimates, with differences becoming clearer when looking at the plots for the more extreme sample sizes.

Let us now compare individual results for the two types of benchmarked estimates. Figure 27 displays ARBs of estimators for the communes with larger sample sizes and Table 15 includes the counts of communes with ARB in each range for each estimator. When benchmarking is carried out at the canton level, ARB reaches 3% or more for 9 communes. However, benchmarking at the national level gives ARBs not exceeding 3% for any commune and smaller than 2% for many communes. Thus, benchmarking at the national level gives better results than at the cantonal level.

Let us now look at Figure 21 and Table 9, showing the corresponding ARB results for the communes with the smallest sample sizes. For these smaller communes, the two benchmarked estimates are very similar and also rather similar to the unadjusted ones, which means that benchmarking at either national or canton level affects only mildly the ARB of the LMM estimates in these communes. In fact, even if this is not visible in this figure due to the range of the y -axis, we saw in Figure 10 that for these communes ($n_d < 25$), benchmarking produces an average reduction in the ARB of a little less half percent point. For the benchmarked LMM estimator at the canton level, ARB exceeds 15% for two of the communes with sample size below 10, but it is kept below 10% for communes with sample sizes over 10, and it does not exceed 5% for communes with sample sizes above 20. Thus, if we do not really require estimates for absolutely all the communes and we want to keep the design bias below 5%, we can give estimates for communes with a sample size of at least 20. If we allow a design-bias of at most 10%, then we could produce estimates for communes with sample sizes of at least 10 units.

The communes with sample sizes below the above mentioned limits could be merged with their nearest neighbor commune according to some closeness criterion such as largest shared boundary for two communes within the same district or within the same canton. In any case, preserving the observations corresponding to the communes with smaller sample sizes when fitting the model, even if model-based estimates are not derived from them, would be better than removing them from the data. In addition, merging those communes with the nearest neighbors would increase the quality of the model-based estimates in the newly created communes due to the larger sample sizes.

5 Application with the real data

Figures 35-60 in Appendix 2 represent, for each of the 26 Swiss cantons respectively, LMM estimates of the commune proportions of actives with benchmarking at the canton level, together with 95% CIs based on the PDB MSE estimators. Estimates are given only for the 2475 communes with non-zero sample size in the Structural survey. CIs tend to be wider for communes with smaller sample sizes, becoming very wide for few communes with extremely small sample sizes. Concretely, in these plots we can find intervals with length clearly exceeding 15% for one commune in Jura, 2 in Valais, few in Ticino, few in Granbunden, one commune in Schwyz and few in Bern, all with sample sizes below 10.

Appendix 3 lists the exact figures of unadjusted LMM estimates with % RRMSE based on PDB for each commune within each canton. Appendixes 4 and 5 list the same LMM estimates with benchmarking at national and canton level respectively. The adjustment factor applied in the benchmarking of LMM estimates at national level equals 1.0075, which means a mild adjustment. Thus, raw LMM estimates of Appendix 3 are very similar to the benchmarked ones of Appendix 4. When benchmarking is done at the canton level, the resulting adjustment factors for each canton are included in Table 6. Despite the slight variation of these adjustment factors across the different cantons, raw and benchmarked LMM estimates listed in Appendixes 3, 4 and 5 turn out to be pretty similar. Figure 15 (left) compares the two types of benchmarked estimates in a line plot.

See that points are around the equality line. When plotting one of the benchmarked estimates against unadjusted LMM ones, the line plot looks very similar to this one. This indicates good design properties of LMM estimates in this application, probably due to a good model fit. On the other hand, when plotting benchmarked LMM estimates against GREG estimates, see Figure 15 (right), we can see that they are rather different. The aligned points at 0 or 1 on the y-axis of this scatterplot correspond to communes with really small sample sizes, for which GREG estimates of the proportions become exactly 0 or 1. The range of variation of GREG estimates is larger, with estimates spread all over the [0, 1] interval. However, except for two communes with smaller estimates, LMM estimates lie within the interval (0.45, 0.8). Thus, LMM estimates are smoothing the GREG estimates, providing more reasonable estimates, which actually do not yield exactly 0 or 1 values for any of the communes.

Table 6: Adjustment factors for benchmarked LMM estimates at the canton level

1	2	3	4	5	6	7	8	9
1.0087	1.0147	1.01	0.9734	1	1.048	0.9804	1.0312	1.0045
10	11	12	13	14	15	16	17	18
1.0004	0.9888	1.0084	1.0026	1.0323	1.0377	1.0289	1.0135	1.008
19	20	21	22	23	24	25	26	
1.0093	1.016	0.9848	1.0069	0.9909	1.0111	1.0114	1.0047	

Finally, for the two types of benchmarked LMM estimates, confidence intervals for all the communes are included in Appendixes 6 and 7. Figure 16 (left) shows boxplots of the lengths of confidence intervals obtained using the three types of LMM estimates, for all communes. The length of CIs seems not to be very much affected by the benchmarking adjustments, being similar for the three types of LMM estimates, with a median CI length around 2.7% and an average length of 3.4%. The maximum length reaches 80% for two communes, concretely communes num. 5307 and 6172, but these two and other lengths taking values over 40% correspond to communes with sample sizes equal to 1. For the communes with sample sizes over 50, the lengths of the CIs is never much greater than 12%, see Figure 16 (right).

Figure 17 additionally compares the lengths of the CIs based on LMM estimates with those based on GREG estimates. Clearly, GREG estimates provide considerably wider CIs with median length over 20% and reaching a length of over 140% for the communes with smallest sample sizes and over 25% for the communes with sample sizes over 50.

To illustrate the differences in RRMSE between benchmarked LMM and GREG estimators, we have plotted in Figure 18 the estimated RRMSEs of these estimators for the communes in Neuchatel, as an example. The RRMSEs of both types of benchmarked LMM estimates have been estimated using the parametric design bootstrap (PDB) procedure. See the drastic reductions in RRMSEs of LMM estimators compared to GREG estimators for all communes from Neuchatel except for few of them, for which there are no great losses. In this canton, the estimated RRMSEs of LMM estimators reach 4% only for the commune with the smallest sample size (< 10) and exceed 2% only for few

communes, whereas the GREG estimators have RRMSEs over 10% for many of the communes and 20% for four of them. This is the tonic for all other cantones in Switzerland although we do not include all the plots here. A summary of the RRMSEs of GREG and the three types of LMM estimates can be seen in the boxplots of Figure 19, for all the communes (left) and for the communes with sample size over 50 (right). These boxplots show the drastic reduction in RRMSE of LMM estimates compared to GREG estimates. In fact, the median reduction in RRMSE of benchmarked LMM estimators at the canton level with respect to the the GREG estimators, calculated as

$$100 \times \text{median}\{\text{RRMSE}(\text{GREG}) - \text{RRMSE}(\text{LMM BM Can}) / \text{RRMSE}(\text{GREG})\},$$

is given by 89.9%. Table 7 includes also the number of communes for which the RRMSEs of GREG and benchmarked LMM estimators at the canton level exceed 1%, 2% and 5% out of the total communes and out of the 677 communes with sample sizes above 100 (where PDB MSE estimates are supposed to be reliable). We can see that there are many more communes with RRMSE below each selected RRMSE level for the benchmarked LMM estimators. Figure 20 displays the boxplots only for the three types of LMM estimates. These boxplots indicate that the benchmarking adjustments seem to have a very mild effect in this application.

To finalize, if one does not want to publish estimates for communes with sample sizes below certain limits, it is useful to know how many communes would be left unestimated. Table 8 lists the number of communes with sample sizes below selected levels in the Structural Survey and also in our simulation study (after removing those with CV above 10%, with sample size equal to 1 and with estimated proportion equal to 1). According to the results of the simulation study in Section 4, if we want to keep the ARB below 5%, we would leave 697 communes without estimates ($n_d \leq 20$). If we allow a 10% ARB, then we would leave 356 communes unestimated ($n_d \leq 10$).

6 Conclusions

The main conclusions that can be drawn from this project are:

- We have obtained a regression model for the indicator of activity that fits quite well the Structural Survey data. Resulting estimates of regression coefficients are meaningful and help to understand the factors that affect the activity/inactivity in Switzerland.
- The obtained model-based estimates (LMM and benchmarked LMM at National and Canton levels) approach the current GREG estimates for areas (districts, communes) with larger sample sizes.
- The median reduction in RRMSE of benchmarked LMM at the canton level with respect to GREG estimators when estimating in communes is 89.9%. LMM estimators reduce the RRMSE in practically all districts and communes, and reductions are specially large for those districts and communes with smaller sample sizes. Lengths of confidence intervals are reduced accordingly.

- Model-based estimates keep the design bias below 5% for the areas with at least 20 observations in the survey and below 10% for the areas of at least 10 observations.
- We have developed two new bootstrap MSE estimates that track acceptably well the design MSE. Simulation results on Phase I of this project indicate that the PDB MSE estimates track well the peaks of the MSE (largest MSE values) without underestimation for areas with sample size larger than 100.

in Phase I of this project, we developed two new bootstrap procedures for estimation of the design MSE of the model-based estimators. The mixed bootstrap (MB) tracks the average design MSE over a group of areas but does not necessarily track the peaks of the MSEs, giving smooth MSE estimators. Similarly, when looking at the coverage of 95% confidence intervals obtained using the MB estimates of the MSE, the nominal 95% was tracked when averaging over groups of communes but not individually for each commune. On the other hand, the parametric design bootstrap (PDB) procedure tracks very well the peaks of the design MSEs without underestimation for communes with sample sizes over 100, but it is more variable, leading to an approximately 5% undercoverage of the confidence intervals. It is important to remark that in the literature of small area estimation no decent procedures for estimation of the design MSE do exist. The only existing estimators for the design MSE are for estimators based on an area level model and have terrible quality (CV that might exceed 400%). Our two bootstrap procedures have an acceptable quality and are still susceptible of improvement in further research.
